

## Module 2

### Iteration, Loop patterns, Strings, Files

#### 2.1 Iteration

Iteration is a processing repeating some task. In a real time programming, we require a set of statements to be repeated certain number of times and/or till a condition is met. Every programming language provides certain constructs to achieve the repetition of tasks. In this section, we will discuss various such looping structures

##### 2.1.1 while Statement

The *while* loop has the syntax as below

```
while condition:
    Statement_1
    Statement_2
    Statement_3
    .....
    Statement_n
Statement_after_while
```

Here, *while* is a keyword. The condition is evaluated first. Till its value remains true, the statement\_1 to statement\_n will be executed. When the condition becomes false, the loop is terminated and statements after the loop will be executed.

Consider an example –

```
n=1
while n<=5:
    print(n)      #observe indentation
    n=n+1
print("over")

output:
1
2
3
4
5
over
```

In the above example, a variable *n* is initialized to 1. Then the condition *n<=5* is being checked as the condition is true, the block of code containing print statement (*print(n)*) and increment statement (*n=n+1*) are executed. After these two lines, condition is checked again. The procedure continues till condition becomes false, that is when *n* becomes 6. Now, the while-loop is terminated and next statement after the loop will be executed. Thus, in this example, the loop is iterated for 5 times..

Note that, a variable *n* is initialized before starting the loop and it is incremented inside the loop. Such a variable that changes its value for every iteration and controls the total

execution of the loop is called as iteration variable or counter variable. If the count variable is not updated properly within the loop, then the loop may not terminate and keeps executing infinitely.

### 2.1.2 Infinite loops, break and continue

A loop may execute infinite number of times when the condition is never going to become false. For example,

```
n=1
while True:
    print(n)
    n=n+1
```

Here, the condition specified for the loop is the constant `True`, which will never get terminated. Sometimes, the condition is given such a way that it will never become false and hence by restricting the program control to go out of the loop. This situation may happen either due to wrong condition or due to not updating the counter variable.

In some situations, we deliberately want to come out of the loop even before the normal termination of the loop. For this purpose `break` statement is used. The following example depicts the usage of `break`. Here, the values are taken from keyboard until a negative number is entered. Once the input is found to be negative, the loop terminates.

```
while True:
    x=int(input("Enter a number:"))
    if x>= 0:
        print("You have entered ",x)
    else:
        print("You have entered a negative number!!")
        break           #terminates the loop
```

#### Output

```
Enter a number:23
You have entered 23
Enter a number:12
You have entered 12
Enter a number:45
You have entered 45
Enter a number:0
You have entered 0
Enter a number:-2
You have entered a negative number!!
```

In the above example, we have used the constant `True` as condition for *while-loop*, which will never become `False`. So, there was a possibility of *infinite loop*. This has been avoided by using `break` statement with a condition. The condition is kept inside the loop such a way that, if the user input is a negative number, the loop terminates. This indicates that, the loop may

terminate with just one iteration (if user gives negative number for the very first time) or it may take thousands of iteration (if user keeps on giving only positive numbers as input). Hence, the number of iterations here is unpredictable. But, we are making sure that it will not be an infinite-loop, instead, the user has control on the loop.

Sometimes, programmer would like to move to next iteration by skipping few statements in the loop, based on some condition. For this purpose continue statement is used. For example, we would like to find the sum of 5 even numbers taken as input from the keyboard. The logic is –

- Read a number from the keyboard
- If that number is odd, without doing anything else, just move to next iteration for reading another number
- If the number is even, add it to sum and increment the accumulator variable.
- When accumulator crosses 5, stop the program

The program for the above task can be written as

```
sum=0
count=0
while True:
    x=int(input("Enter a number:"))
    if x%2 !=0:
        continue
    else:
        sum+=x
        count+=1

        if count==5:
            break

print("Sum= ", sum)
```

output

```
Enter a number:13
Enter a number:12
Enter a number:4
Enter a number:5
Enter a number:-3
Enter a number:8
Enter a number:7
Enter a number:16
Enter a number:6
```

### 2.1.3 Definite loops using for

The while loop iterates till the condition is met and hence, the number of iterations are usually unknown prior to the loop. Hence, it is sometimes called as indefinite loop. When we know total number of times the set of statements to be executed, for loop will be used. This

is called as a definite loop. The for-loop iterates over a set of numbers, a set of words, lines in a file etc. The syntax of for-loop would be

```
for var in list/sequence:
    statement_1
    statement_2
    statement_3

statements_after_for
```

Here, **for** and **in** are keywords:

<b>list/sequence</b>	is a set of elements on which loop is iterated. That is the loop will be executed till there is an element in the list/sequence constitutes body of loop.
<b>statements</b>	constitutes body of the loop

Ex: In the below given example, a list `names` containing three strings has been created. Then the counter variable `x` in the for-loop iterates over this list. The variable `x` takes the elements in `names` one by one and the body of the loop is executed

```
names=[ "Ram", "Shyam", "Bheem" ]
for x in names:
    Print(x)
```

Output:

```
Ram
Shyam
Bheem
```

NOTE: In Python, list is an important data type. It can take a sequence of elements of different types. It can take values as a comma separated sequence enclosed within square brackets. Elements in the list can be extracted using index (just similar to extracting array elements in C/C++ language). Various operations like indexing, slicing, merging, addition and deletion of elements etc. can be applied on lists. The details discussion on Lists will be done in Module 3.

The for loop can be used to print (or extract) all the characters in a string as shown below –

```
for i in "Hello"
    print(i,end='\t')
```

output:

```
H e l l o
```

When we have a fixed set of numbers to iterate in a for loop, we can use a function `range()`. The function `range()` takes the following format –

```
range(start, end, steps)
```

The `start` and `end` indicates starting and ending values in the sequence, where `end` is excluded in the sequence (That is, sequence is up to `end-1`). The default value of `start` is 0. The argument `steps` indicates the increment/decrement in the values of sequence with the default value as 1. Hence, the argument `steps` is optional. Let us consider few examples on usage of `range()` function.

**Ex 1: Printing the values from 0 to 4 –**

```
for i in range(5)
    print(i, end= '\t')
```

output:

0      1      2      3      4      5

Here, 0 is the default starting value. The statement `range(5)` is same as `range(0,5)` and `range(0,5,1)`.

**Ex 2: Printing the values from 5 to 1**

```
for i in range(5,0,-1)
    print(i, end= '\t')
```

output:

5      4      3      2      1

The function `range(5,0,-1)` indicates that the sequence of values are 5 to 0(excluded) in steps of -1 (downwards).

**Ex 3: Printing only even numbers less than 10**

```
for i in range(0,10,2):
    print(i, end= '\t')
```

**Output:**

0      2      4      6      8

**2.1.4 Loop patterns**

The while-loop and for-loop are usually used to go through a list of items or the contents of a file and to check maximum or minimum data value. These loops are generally constructed by the following procedure –

- Initializing one or more variables before the loop starts
- Performing some computation on each item in the loop body, possibly changing the variables in the body of the loop
- Looking at the resulting variables when the loop completes

The construction of these loop patterns are demonstrated in the following examples.

### 2.1.4.1 counting and summing loops

One can use the *for* loop for counting number of items in the list as shown

```
count = 0
for i in [4, -2, 41, 34, 25]:
    count = count + 1
print("Count:", count)
```

Here, the variable *count* is initialized before the loop. Though the counter variable *i* is not being used inside the body of the loop, it controls the number of iterations. The variable *count* is incremented in every iteration, and at the end of the loop the total number of elements in the list is stored in it.

One more loop similar to the above is finding the sum of elements in the list

```
total = 0
for x in [4, -2, 41, 34, 25]:
    total = total + x
print("Total:", total)
```

Here, the variable *total* is called as accumulator because in every iteration, it accumulates the sum of elements. In each iteration, this variable contains running total of values so far.

*NOTE: In practice, both of the counting and summing loops are not necessary, because there are built-in functions `len()` and `sum()` for the same tasks respectively.*

**Maximum and Minimum Loops:** To find maximum element in the list, the following code can be used –

```
big = None
print('Before Loop:', big)
for x in [12, 0, 21, -3]:
    if big is None or x > big :
        big = x
    print('Iteration Variable:', x, 'Big:', big)

print('Biggest:', big)
```

Output:

```
Before Loop: None
Iteration Variable: 12 Big: 12
Iteration Variable: 0 Big: 12
Iteration Variable: 21 Big: 21
Iteration Variable: -3 Big: 21
Biggest: 21
```

Here, we initialize the variable `big` to `None`. It is a special constant indicating empty. Hence, we cannot use relational operator `==` while comparing it with `big`. Instead, the `is` operator must be used. In every iteration, the counter variable `x` is compared with previous value of `big`. If `x > big`, then `x` is assigned to `big`.

Similarly, one can have a loop for finding smallest of elements in the list as given below-

```
small = None
print('Before Loop:', small)
for x in [12, 0, 21, -3]:
    if small is None or x < small :
        small = x
    print('Iteration Variable:', x, 'Small:', small)

print('Smallest:', small)
```

#### Output:

```
Before Loop: None
Iteration Variable: 12 Small: 12
Iteration Variable: 0 Small: 0
Iteration Variable: 21 Small: 0
Iteration Variable: -3 Small: -3
Smallest: -3
```

**NOTE:** In Python, there are built-in functions `max()` and `min()` to compute maximum and minimum values among. Hence, the above two loops need not be written by the programmer explicitly. The inbuilt function `min()` has the following code in Python.

```
def min(values):
    smallest = None
    for value in values:
        if smallest is None or value < smallest:
            smallest = value
    return smallest
```

## 2.2 STRINGS

A string is a sequence of characters, enclosed either within a pair of single quotes or double quotes. Each character of a string corresponds to an index number, starting with zero as shown below.

st= "Hello World"

character	H	e	l	l	o		W	o	r	l	d
index	0	1	2	3	4	5	6	7	8	9	10

The characters of a string can be accessed using index enclosed within square brackets. For example,

```

>>> word1="Hello"
>>> word2='hi'
>>> x=word1[1]      #2nd character of word1 is extracted
>>> print(x)

e
>>> y=word2[0]      #1st character of word1 is extracted
>>> print(y)

h

```

Python supports negative indexing of string starting from the end of the string as shown Below

st= "Hello World"

character	H	e	l	l	o		W	o	r	l	d
Negative Index	-11	-10	-9	-8	-7	-6	-5	-4	-3	-2	-1

The characters can be extracted using negative index also. For example

```

>>> var="Hello"
>>> print(var[-1])
o
>>> print(var[-4])
e

```

Whenever the string is too big to remember last positive index, one can use negative index to extract characters at the end of string.

### 2.2.1 Getting Length of a String using len( )

The len() function can be used to get length of a string.

```

>>> var="Hello"
>>> ln=len(var)
>>> print(ln)

5

```

The index for string varies from 0 to length-1. Trying to use the index value beyond this range generates error.

```

>>> var="Hello"
>>> ln=len(var)
>>> ch=var[ln]
IndexError: string index out of range

```

### 2.2.2 Traversal through String with a Loop

Extracting every character of a string one at a time and then performing some action on that character is known as traversal. A string can be traversed either using while loop or using for loop in different ways. Few of such methods is shown here

```
#Using for loop:

st="Hello"
for i in st:
    print(i, end='\t')

Output:
H e l l o
```

In the above example, the *for* loop is iterated from first to last character of the string *st*. That is, in every iteration, the counter variable *i* takes the values as H, e, l, l and o. The loop terminates when no character is left in *st*.

```
#Using while loop:

st="Hello"
i=0
while i<len(st):
    print(st[i], end='\t')
    i+=1

Output:
H e l l o
```

In this example, the variable *i* is initialized to 0 and it is iterated till the length of the string. In every iteration, the value of *i* is incremented by 1 and the character in a string is extracted using *i* as index

### 2.2.3 String Slices

A segment or a portion of a string is called as slice. Only a required number of characters can be extracted from a string using colon (:) symbol. The basic syntax for slicing a string would be –

```
st[i:j:k]
```

This will extract character from *i*<sup>th</sup> character of *st* till (*j*–1)<sup>th</sup> character in steps of *k*. If first index *i* is not present, it means that slice should start from the beginning of the string. If the second index *j* is not mentioned, it indicates the slice should be till the end of the string. The third parameter *k*, also known as stride, is used to indicate number of steps to be incremented after extracting first character. The default value of stride is 1.

Consider following examples along with their outputs to understand string slicing.

St="Hello World"											
character	H	e	l	l	o		W	o	r	l	d
index	0	1	2	3	4	5	6	7	8	9	10

#refer this string for all examples

1. `print("st[:] is", st[:])` #output **Hello World**  
As both index values are not given, it assumed to be a full string.
2. `print("st[0:5] is ", st[0:5])` #output is Hello  
Starting from 0<sup>th</sup> index to 4<sup>th</sup> index (5 is exclusive), characters will be printed
3. `print("st[0:5:1] is", st[0:5:1])` #output is Hello  
This code also prints characters from 0<sup>th</sup> to 4<sup>th</sup> index in the steps of 1. Comparing this example with previous example, we can make out that when the stride value is 1, it is optional to mention.
4. `print("st[3:8] is ", st[3:8])` #output is lo Wo  
Starting from 3<sup>rd</sup> index to 7<sup>th</sup> index (8 is exclusive), characters will be printed
5. `print("st[7:] is ", st[7:])` #output is orld  
Starting from 7<sup>th</sup> index to till the end of string, characters will be printed.
6. `print(st[::2])` #outputs HloWrld  
This example uses stride value as 2. So, starting from first character, every alternative character (char+2) will be printed.
7. `print("st[4:4] is ", st[4:4])` #gives empty string  
Here, st[4:4] indicates, slicing should start from 4<sup>th</sup> character and end with (4-1)=3<sup>rd</sup> character, which is not possible. Hence the output would be an empty string.
8. `print(st[3:8:2])` #output is l o  
Starting from 3<sup>rd</sup> character, till 7<sup>th</sup> character, every alternative index is considered.
9. `print(st[1:8:3])` #output is eoo  
Starting from index 1, till 7<sup>th</sup> index, every 3<sup>rd</sup> character is extracted here.
10. `print(st[-4:-1])` #output is orl  
Refer the diagram of negative indexing given earlier. Excluding the -1<sup>st</sup> character, all characters at the indices -4, -3 and -2 will be displayed. Observe the role of stride with default value 1 here. That is, it is computed as -4+1=-3, -3+1=-2 etc.
11. `print(st[-1:])` #output is d  
Here, starting index is -1, ending index is not mentioned (means, it takes the index 10) and the stride is default value 1. So, we are trying to print characters from -1 (which is the last character of negative indexing) till 10<sup>th</sup> character (which is also the last character in positive indexing) in incremental order of 1. Hence, we will get only last character as output.
12. `print(st[:-1])` #output is Hello Worl  
Here, starting index is default value 0 and ending is -1 (corresponds to last character in negative indexing). But, in slicing, as last index is excluded always, -1<sup>st</sup> character is omitted and considered only up to -2<sup>nd</sup> character.

13. `print(st[:])` #outputs Hello World

Here, two colons have used as if stride will be present. But, as we haven't mentioned stride its default value 1 is assumed. Hence this will be a full string.

14. `print(st[::-1])` #outputs dlrow olleH

This example shows the power of slicing in Python. Just with proper slicing, we could able to reverse the string. Here, the meaning is a full string to be extracted in the order of -1. Hence, the string is printed in the reverse order.

15. `print(st[::-2])` #output is drWoH

Here, the string is printed in the reverse order in steps of -2. That is, every alternative character in the reverse order is printed. Compare this with example (6) given above.

By the above set of examples, one can understand the power of string slicing and of Python script. The slicing is a powerful tool of Python which makes many task simple pertaining to data types like strings, Lists, Tuple, Dictionary etc. (Other types will be discussed in later Modules)

### 2.2.4 Strings are Immutable

The objects of string class are immutable. That is, once the strings are created (or initialized), they cannot be modified. No character in the string can be edited/deleted/added. Instead, one can create a new string using an existing string by imposing any modification required.

Try to attempt following assignment –

```
>>> st= "Hello World"
```

```
>>> st[3]='t'
```

```
TypeError: 'str' object does not support item assignment
```

Here, we are trying to change the 4th character (index 3 means, 4th character as the first index is 0) to t. The error message clearly states that an assignment of new item (a string) is not possible on string object. So, to achieve our requirement, we can create a new string using slices of existing string as below –

```
>>> st= "Hello World"
```

```
>>> st1= st[:3]+ 't' + st[4:]
```

```
>>> print(st1)
```

```
Helto World      #l is replaced by t in new string st1
```

### 2.2.5 Looping and Counting

Using loops on strings, we can count the frequency of occurrence of a character within another string. The following program demonstrates such a pattern on computation called as a counter. Initially, we accept one string and one character (single letter). Our aim to find the total number of times the character has appeared in string. A variable count is initialized to zero, and incremented each time a character is found. The program is given below –

```
def countChar(st,ch):
    count=0
    for i in st:
        if i==ch:
            count+=1
    return count

st=input("Enter a string:")
ch=input("Enter a character to be counted:")
c=countChar(st,ch)
print("{0} appeared {1} times in {2}".format(ch,c,st))
```

**Sample Output:**

```
Enter a string: hello how are you?
Enter a character to be counted: h
h appeared 2 times in hello how are you?
```

## 2.2.6 The in Operator

The in operator of Python is a Boolean operator which takes two string operands. It returns True, if the first operand appears in second operand, otherwise returns False. For example,

```
>>> 'el' in 'hello' #el is found in hello
True
>>> 'x' in 'hello' #x is not found in hello
False
```

## 2.2.7 String Comparison

Basic comparison operators like < (less than), > (greater than), == (equals) etc. can be applied on string objects. Such comparison results in a Boolean value True or False. Internally, such comparison happens using ASCII codes of respective characters. Consider following examples –

Ex1:

```
st= "hello"
if st== 'hello':
    print('same')
```

Output  
same

Ex2:

```
st= "hello"
if st<= 'Hello':
    print('lesser')
else:
    print('greater')
```

output  
greater

Output is greater. The ASCII value of h is greater than ASCII value of H. Hence, hello is greater than Hello.

**NOTE:** A programmer must know ASCII values of some of the basic characters. Here are few –

A – Z : 65 – 90  
 a – z : 97 – 122  
 0 – 9 : 48 – 57  
 Space : 32  
 Enter Key : 13

## 2.2.8 String Methods

String is basically a class in Python. When we create a string in our program, an object of that class will be created. A class is a collection of member variables and member methods (or functions). When we create an object of a particular class, the object can use all the members (both variables and methods) of that class. Python provides a rich set of built-in classes for various purposes. Each class is enriched with a useful set of utility functions and variables that can be used by a Programmer. A programmer can create a class based on his/her requirement, which are known as user-defined classes.

The built-in set of members of any class can be accessed using the dot operator as shown–

`objName.memberMethod(arguments)`

The dot operator always binds the member name with the respective object name. This is very essential because, there is a chance that more than one class has members with same name. To avoid that conflict, almost all Object oriented languages have been designed with this common syntax of using dot operator. (Detailed discussion on classes and objects will be done in later Modules.)

Python provides a function (or method) `dir` to list all the variables and methods of a particular class object. Observe the following statements –

```
>>> s="hello"    #string object is created with the name s
>>> type(s)      #checking type of s
<class 'str'>    #s is object of type class str
>>> dir(s)       #display all methods and variables of object s

['_add_', '_class_', '_contains_', '_delattr_',
'_dir_', '_doc_', '_eq_', '_format_', '_ge_',
'_getattribute_', '_getitem_', '_getnewargs_', '_gt_',
'_hash_', '_init_', '_init_subclass_', '_iter_',
'_le_', '_len_', '_lt_', '_mod_', '_mul_', '_ne_',
'_new_', '_reduce_', '_reduce_ex_', '_repr_',
'_rmod_', '_rmul_', '_setattr_', '_sizeof_', '_str_',
'_subclasshook_', 'capitalize', 'casefold', 'center',
'count', 'encode', 'endswith', 'expandtabs', 'find', 'format',
'format_map', 'index', 'isalnum', 'isalpha', 'isdecimal',
'isdigit', 'isidentifier', 'islower', 'isnumeric',
'isprintable', 'isspace', 'istitle', 'isupper', 'join',
'ljust', 'lower', 'lstrip', 'maketrans', 'partition',
'replace', 'rfind', 'rindex', 'rjust', 'rpartition', 'rsplit',
rstrip', 'split', 'splitlines', 'startswith', 'strip',
'swapcase', 'title', 'translate', 'upper', 'zfill']
```

### Students need not remember the above list !!

*Note* that, the above set of variables and methods are common for any object of string class that we create. Each built-in method has a predefined set of arguments and return type. To know the usage, working and behavior of any built-in method, one can use the command `help`. For example, if we would like to know what is the purpose of `islower()` function (refer above list to check its existence!!), how it behaves etc, we can use the statement –

```
>>> help(str.islower)
Help on method_descriptor:
```

```
islower(...)
    S.islower() -> bool
```

Return True if all cased characters in S are lowercase and there is at least one cased character in S, False otherwise.

This is built-in help-service provided by Python. Observe the `className.memberName` format while using *help*.

The methods are usually called using the object name. This is known as method invocation. We say that a method is invoked using an object.

Now, we will discuss some of the important methods of string class.

1. **`capitalize(s)`** : This function takes one string argument `s` and returns a capitalized version of that string. That is, the first character of `s` is converted to upper case, and all other characters to lowercase. Observe the examples given below –

Ex1	<pre>&gt;&gt;&gt; s="hello" &gt;&gt;&gt; s1=str.capitalize(s) &gt;&gt;&gt; print(s1) Hello      #1st character is changed to uppercase</pre>
Ex2	<pre>&gt;&gt;&gt; s="hello World" &gt;&gt;&gt; s1=str.capitalize(s) &gt;&gt;&gt; print(s1) Hello world</pre>

Observe in Ex2 that the first character is converted to uppercase, and an in-between uppercase letter W of the original string is converted to lowercase.

2. **`s.upper()`** : This function returns a copy of a string `s` to uppercase. As strings are immutable, the original string `s` will remain same.

```
>>> st= "hello"
>>> st1=st.upper()
>>> print(st1)
'HELLO'
>>> print( st)      #no change in original string
'hello'
```

3. **`s.lower()`** : This method is used to convert a string `s` to lowercase. It returns a copy of original string after conversion, and original string is intact.

```
>>> st='HELLO'
>>> st1=st.lower()
>>> print(st1)
hello
>>> print(st) #no change in original
string
HELLO
```

4. `s.find(s1)` : The `find()` function is used to search for a substring `s1` in the string `s`. If found, the index position of first occurrence of `s1` in `s`, is returned. If `s1` is not found in `s`, then `-1` is returned.

```
>>> st='hello'
>>> i=st.find('l')
>>> print(i) #output is 2
>>> i=st.find('lo')
>>> print(i) #output is 3
>>> print(st.find('x')) #output is -1
```

The `find()` function can take one more form with two additional arguments viz. start and end positions for search.

```
>>> st="calender of Feb. cal of march"
>>> i= st.find('cal')
>>> print(i) #output is 0
```

Here, the substring `'cal'` is found in the very first position of `st`, hence the result is 0.

```
>>> i=st.find('cal',10,20)
>>> print(i) #output is 17
```

Here, the substring `cal` is searched in the string `st` between 10th and 20th position and hence the result is 17.

```
>>> i=st.find('cal',10,15)
>>> print(i) #ouput is -1
```

In this example, the substring `'cal'` has not appeared between 10<sup>th</sup> and 15<sup>th</sup> character of `st`. Hence, the result is -1.

5. `s.strip()`: Returns a copy of string `s` by removing leading and trailing white spaces.

```
>>> st=" hello world "  
>>> st1 = st.strip()  
>>> print(st1)  
hello world
```

The `strip()` function can be used with an argument `chars`, so that specified chars are removed from beginning or ending of `s` as shown below

```
>>> st="###Hello##"  
>>> st1=st.strip('#')  
>>> print(st1)      #all hash symbols are removed  
Hello
```

We can give more than one character for removal as shown below

```
>>> st="Hello world"  
>>> st.strip("Hld")  
ello wor
```

6. `S.startswith(prefix, start, end)`: This function has 3 arguments of which `start` and `end` are option. This function returns `True` if `S` starts with the specified `prefix`, `False` otherwise.

```
>>> st="hello world"  
>>> st.startswith("he") #returns True
```

When `start` argument is provided, the search begins from that position and returns `True` or `False` based on search result.

```
>>> st="hello world"  
>>> st.startswith("w",6) #True because w is at 6th position
```

When both `start` and `end` arguments are given, search begins at `start` and ends at `end`.

```
>>> st="xyz abc pqr ab mn gh"  
>>> st.startswith("pqr ab mn",8,12) #returns False  
>>> st.startswith("pqr ab mn",8,18) #returns True
```

The `startswith( )` function requires case of the alphabet to match. So, when we are not sure about the case of the argument, we can convert it to either upper case or lowercase and then use `startswith( )` function as below –

```
>>> st="Hello"  
>>> st.startswith("he") #returns False  
>>> st.lower().startswith("he") #returns True
```

7. `S.count(s1, start, end)`: The `count()` function takes three arguments – string, starting position and ending position. This function returns the number of non-overlapping occurrences of substring `s1` in string `S` in the range of `start` and `end`.

```
>>> st="hello how are you? how about you?"
>>> st.count('h') #output is 3
>>> st.count('how') #output is 2
>>> st.count('how',3,10) #output is 1 because of range given
```

8. `isdigit()`: method returns `True` if all the characters are digits, otherwise `False`.

```
txt = "50800"
x = txt.isdigit()
print(x) # output returns True
```

9. `title()`: method returns a string where the first character in every word is upper case. Like a header, or a title.

```
txt = "Welcome to my 2nd world"
x = txt.title()
print(x) #Welcome To My 2Nd World
```

10. `center()`: method will center align the string, using a specified character (space is default) as the fill character.

```
txt = "banana"
x = txt.center(20)
print(x) #          banana
```

**There are many more built-in methods for string class. Students are advised to explore more for further study**

### 2.2.9 Parsing Strings

Sometimes, we may want to search for a substring matching certain criteria. For example, finding domain names from email-Ids in the list of messages is a useful task in some projects.

Consider a string below and we are interested in extracting only the domain name.

```
From s.rajatha07@gmail.com Sat Jan 5 09:14:16 2020
```

- Now, our aim is to extract only **gmail.com**, which is the domain name. We can think of logic as–
  - Identify the position of `@`, because all domain names in email IDs will be after the symbol `@`

- Identify a white space which appears after @ symbol, because that will be the end of domain name.
- Extract the substring between @ and white-space

The concept of string slicing and find() function will be useful here. Consider the code given below.

```
>>> atpos=s.find('@')
>>> print(atpos)
16
>>> spos=s.find(' ',atpos)
>>> print(spos)
26
>>> host=data[atpos+1:spos]    #slicing from @ till white-space
>>> print(host)
gmail.com
```

## 2.2.10 Format operator

The format operator, % allows us to construct strings, replacing parts of the strings with the data stored in variables. The first operand is the format string, which contains one or more format sequences that specify how the second operand is formatted. The result is a string.

```
>>> sum=20
>>> '%d' %sum
'20' #string '20', but not integer 20
```

*Note* that, when applied on both integer operands, the % symbol acts as a modulus operator. When the first operand is a string, then it is a format operator. Consider few examples illustrating usage of format operator.

**Ex1.** >>> "The sum value %d is originally integer" %sum  
The sum value 20 is originally integer'

**Ex2.** >>> '%d %f %s'%(3,0.5,'hello')  
'3 0.500000 hello'

**Ex3.** >>> '%d %g %s'%(3,0.5,'hello')  
'3 0.5 hello'

**Ex4.** >>> '%d'% 'hello'  
TypeError: %d format: a number is required, not str

**Ex5.** >>> '%d %d %d'%(2,5)  
TypeError: not enough arguments for format string

## 2.3 Files

File handling is an important requirement of any programming language, as it allows us to store the data permanently on the secondary storage and read the data from a permanent source. Here, we will discuss how to perform various operations on files using the programming language Python.

### 2.3.1 Persistence

The programs that we have considered till now are based on console I/O. That is, the input was taken from the keyboard and output was displayed onto the monitor. When the data to be read from the keyboard is very large, console input becomes a laborious job. Also, the output or result of the program has to be used for some other purpose later, it has to be stored permanently. Hence, reading/writing from/to files are very essential requirement of programming.

We know that the programs stored in the hard disk are brought into main memory to execute them. These programs generally communicate with CPU using conditional execution, iteration, functions etc. But, the content of main memory will be erased when we turn-off our computer. We have discussed these concepts in Module1 with the help of Figure 2.1. Here we will discuss about working with secondary memory or files. The files stored on the secondary memory are permanent and can be transferred to other machines using pen-drives/CD.

### 2.3.2 Opening Files

To perform any operation on a file, one must open a file. File opening involves communication with operating system. In Python, a file can be opened using a built-in function `open()`. While opening a file, we must specify the name of the file to be opened. Also, we must inform the OS about the purpose of opening a file, which is termed as file opening mode. The syntax of `open()` function is as below –

```
fhand= open("filename", "mode")
```

Here,

<b>filename</b>	is name of the file to be opened. This string may be just a name of the file, or it may include pathname also. Pathname of the file is optional when the file is stored in current working directory
<b>mode</b>	This string indicates the purpose of opening a file. It takes a predefined set of values as given in Table 2.1
<b>fhand</b>	It is a reference to an object of file class, which acts as a handler or tool for all further operations on files.

When our Python program makes a request to open a specific file in a particular mode, then OS will try to serve the request. When a file gets opened successfully, then a file object is returned. This is known as file handle and is as shown in Figure 2.1. It will help to perform various operations on a file through our program. If the file cannot be opened due to some reason, then error message (traceback) will be displayed.

Figure 2.1 File handle

A file opening may cause an error due to some of the reasons as listed below –

- File may not exist in the specified path (when we try to read a file)
- File may exist, but we may not have a permission to read/write a file
- File might have got corrupted and may not be in an opening state

Since, there is no guarantee about getting a file handle from OS when we try to open a file, it is always better to write the code for file opening using try-except block. This will help us to manage error situation.

Mode	Meaning
r	Opens a file for reading purpose. If the specified file does not exist in the specified path, or if you don't have permission, error message will be displayed. This is the default mode of <i>open()</i> function in Python.
w	Opens a file for writing purpose. If the file does not exist, then a new file with the given name will be created and opened for writing. If the file already exists, then its content will be over-written.
a	Opens a file for appending the data. If the file exists, the new content will be appended at the end of existing content. If no such file exists, it will be created and new content will be written into it.
r+	Opens a file for reading and writing.
w+	Opens a file for both writing and reading. Overwrites the existing file if the file exists. If the file does not exist, creates a new file for reading and writing.
a+	Opens a file for both appending and reading. The file pointer is at the end of the file if the file exists. The file opens in the append mode. If the file does not exist, it creates a new file for reading and writing.
rb	Opens a file for reading only in binary format
wb	Opens a file for writing only in binary format
ab	Opens a file for appending only in binary format

### 2.3.3 Text Files and Lines

A text file is a file containing a sequence of lines. It contains only the plain text without any images, tables etc. Different lines of a text file are separated by a newline character `\n`. In the text files, this newline character may be invisible, but helps in identifying every line in the file. There will be one more special entry at the end to indicate end of file (EOF).

**NOTE:** There is one more type of file called binary file, which contains the data in the form of bits. These files are capable of storing text, image, video, audio etc. All these data will be stored in the form of a group of bytes whose formatting will be known. The supporting program can

interpret these files properly, whereas when opened using normal text editor, they look like messy, unreadable set of characters.

### 2.3.4 Reading Files

When we successfully open a file to read the data from it, the `open()` function returns the file handle (or an object reference to file object) which will be pointing to the first character in the file. A text file containing lines can be iterated using a for-loop starting from the beginning with the help of this file handle. Consider the following example of counting number of lines in a file.

**NOTE:** Before executing the below given program, create a text file (using Notepad or similar editor) `myfile.txt` in the current working directory (The directory where you are going to store your Python program). Open this text file and add few random lines to it and then close. Now, open a Python script file, say `countLines.py` and save it in the same directory as that of your text file `myfile.txt`. Then, type the following code in Python script `countLines.py` and execute the program. (You can store text file and Python script file in different directories. But, if you do so, you have to mention complete path of text file in the `open()` function.)

*Sample Text file myfile.txt:*

```
hello how are you?  
I am doing fine  
what about you?
```

**#Python script file countLines.py**

```
fhand=open('myfile.txt','r')  
count =0  
for line in fhand:  
    count+=1  
    print("Line Number ",count, ":", line)  
print("Total lines=",count)  
fhand.close()
```

output:

```
Line Number 1 : hello how are you?  
Line Number 2 : I am doing fine  
Line Number 3 : what about you?  
Total lines= 3
```

In the above program, initially, we will try to open the file `'myfile.txt'`. As we have already created that file, the file handler will be returned and the object reference to this file will be stored in `fhand`. Then, in the for-loop, we are using `fhand` as if it is a sequence of lines. For each line in the file, we are counting it and printing the line. In fact, a line is identified internally with the help of new-line character present at the end of each line.

Though we have not typed `\n` anywhere in the file `myfile.txt`, after each line, we would have pressed enter-key. This act will insert a `\n`, which is invisible when we view the file through notepad. Once all lines are over, `fhand` will reach end-of-file and hence terminates the loop.

Note that, when end of file is reached (that is, no more characters are present in the file), then an attempt to read will return `None` or empty character `''` (two quotes without space in between).

Once the operations on a file is completed, it is a practice to close the file using a function `close()`. Closing of a file ensures that no unwanted operations are done on a file handler. Moreover, when a file was opened for writing or appending, closure of a file ensures that the last bit of data has been uploaded properly into a file and the end-of-file is maintained properly. If the file handler variable (in the above example, `fhand`) is used to assign some other file object (using `open()` function), then Python closes the previous file automatically.

If you run the above program and check the output, there will be a gap of two lines between each of the output lines. This is because, the new-line character `\n` is also a part of the variable line in the loop, and the `print()` function has default behavior of adding a line at the end (due to default setting of end parameter of `print()`). To avoid this double-line spacing, we can remove the new-line character attached at the end of variable line by using built-in string function `rstrip()` as below.

```
print("Line Number ",count, ":", line.rstrip())
```

It is obvious from the logic of above program that from a file, each line is read one at a time, processed and discarded. Hence, there will not be a shortage of main memory even though we are reading a very large file. But, when we are sure that the size of our file is quite small, then we can use `read()` function to read the file contents. This function will read entire file content as a single string. Then, required operations can be done on this string using built-in string functions. Consider the below given example—

```
fhand=open('myfile.txt')
s=fhand.read()
print("Total number of characters:",len(s))
print("String up to 20 characters:", s[:20])
```

After executing above program using previously created file `myfile.txt`, then the output would be—

```
Total number of characters:50
String up to 20 characters: hello how are you?
I
```

### 2.3.5 Writing Files

To write a data into a file, we need to use the mode `w` in `open()` function.

```
>>> fhand=open("mynewfile.txt","w")
>>> print(fhand)
<_io.TextIOWrapper name='mynewfile.txt' mode='w' encoding='utf-8'>
```

If the file specified already exists, then the old contents will be erased and it will be ready to write new data into it. If the file does not exist, then a new file with the given name will be created.

The `write()` method is used to write data into a file. This method returns number of characters successfully written into a file. For example,

```
>>> s="hello how are you?"
>>> fhand.write(s)
18
```

Now, the file object keeps track of its position in a file. Hence, if we write one more line into the file, it will be added at the end of previous line. Here is a complete program to write few lines into a file

```
fhand=open('f1.txt','w')
for i in range(5):
    line=input("Enter a line: ")
    fhand.write(line+"\n")

fhand.close()
```

The above program will ask the user to enter 5 lines in a loop. After every line has been entered, it will be written into a file. Note that, as `write()` method doesn't add a new-line character by its own, we need to write it explicitly at the end of every line. Once the loop gets over, the program terminates. Now, we need to check the file `f1.txt` on the disk (in the same directory where the above Python code is stored) to find our input lines that have been written into it.

### 2.3.6 Searching through a file

Most of the times, we would like to read a file to search for some specific data within it. This can be achieved by using some string methods while reading a file. For example, we may be interested in printing only the line which starts with a character `h`. Then we can use `startswith()` method.

```
fhand=open('myfile.txt')
for line in fhand:
    if line.startswith('h'):
        print(line)

fhand.close()
```

Assume the input file `myfile.txt` is containing the following lines –

```
hello how are you?
I am doing fine
how about you?
```

Now, if we run the above program, we will get the lines which starts with `h` –

```
hello how are you?
how about you?
```

### 2.3.7 Letting the user choose file name

In a real time programming, it is always better to ask the user to enter a name of the file which he/she would like to open, instead of hard-coding the name of a file inside the program.

```
fname=input("Enter a file name:")
fhand=open(fname)
count =0
for line in fhand:
    count+=1
    print("Line Number ",count, ":", line)
print("Total lines=",count)
```

```
fhand.close()
```

In this program, the user input filename is received through variable `fname`, and the same has been used as an argument to `open()` method. Now, if the user input is `myfile.txt` (discussed before), then the result would be.

```
Total lines=3
```

Everything goes well, if the user gives a proper file name as input. But, what if the input filename cannot be opened (Due to some reason like – file doesn't exist, file permission denied etc)? Obviously, Python throws an error. The programmer needs to handle such runtime errors as discussed in the next section.

### 2.3.8 using try, except to open a file

It is always a good programming practice to write the commands related to file opening within a try block. Because, when a filename is a user input, it is prone to errors. Hence, one should handle it carefully. The following program illustrates this.

```
fname=input("Enter a file name:")
try:
    fhand=open(fname)
except:
    print("File cannot be opened")
    exit()

count =0
for line in fhand:
    count+=1
    print("Line Number ",count, ":", line)

print("Total lines=",count)
fhand.close()
```

In the above program, the command to open a file is kept within try block. If the specified file cannot be opened due to any reason, then an error message is displayed saying File cannot be opened, and the program is terminated. If the file could be opened successfully, then we will proceed further to perform required task using that file.

### 2.3.9 Debugging

While performing operations on files, we may need to extract required set of lines or words or characters. For that purpose, we may use string functions with appropriate delimiters that may exist between the words/lines of a file. But, usually, the invisible characters like white space, tabs and new-line characters are confusing and it is hard to identify them properly. For example,

```
>>> s="1 2\t 3\n 4"
>>> print(s)
1 2 3
4
```

Here, by looking at the output, it may be difficult to make out where there is a space, where is a tab etc. Python provides a utility function called as `repr()` to solve this problem. This method takes any object as an argument and returns a string representation of that object. For example, the `print()` in the above code snippet can be modified as –

```
>>> print(repr(s))  
'1 2\t 3\n 4'
```

Note that, some of the systems use `\n` as new-line character, and few others may use `\r` (carriage return) as a new-line character. The `repr()` method helps in identifying that too.
